Game playing

Chapter 5, Sections 1–5

Outline

- \Leftrightarrow Perfect play \Leftrightarrow Resource limits \Leftrightarrow α - β pruning
- \diamondsuit Games of chance

Games vs. search problems

"Unpredictable" opponent \Rightarrow solution is a contingency plan

Time limits \Rightarrow unlikely to find goal, must approximate

Plan of attack:

- algorithm for perfect play (Von Neumann, 1944)
- finite horizon, approximate evaluation (Zuse, 1945; Shannon, 1950; Samuel, 1952-57)
- pruning to reduce costs (McCarthy, 1956)

Types of games

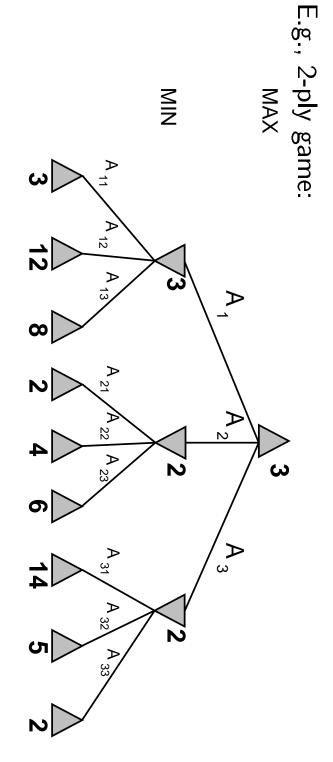

imperfect information	perfect information	
	chess, checkers, go, othello	deterministic
bridge, poker, scrabble nuclear war	backgammon monopoly	chance

Minimax

Perfect play for deterministic, perfect-information games

Idea: choose move to position with highest minimax value

= best achievable payoff against best play

Minimax algorithm

```
function MINIMAX-VALUE(state, game) returns a utility value
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        function Minimax-Decision(game) returns an operator
                                                                                                                                                                                                                                                                                                                                                                                               return the op with the highest Value[op]
                                                                                                                                           else if MAX is to move in state then
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          for each op in Operators[game] do
                                                                                                                                                                                                                                     if Terminal-Test[game](state) then
return the lowest MINIMAX-VALUE of SUCCESSORS(state)
                                                                                           return the highest MINIMAX-VALUE of SUCCESSORS(state)
                                                                                                                                                                                    return UTILITY[game](state)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          Value[op] \leftarrow Minimax-Value(Apply(op, game), game)
```

Properties of minimax

Complete??

Optimal??

Time complexity??

Space complexity??

Properties of minimax

Complete?? Yes, if tree is finite (chess has specific rules for this)

Optimal?? Yes, against an optimal opponent. Otherwise??

Time complexity?? $O(b^m)$

Space complexity?? O(bm) (depth-first exploration)

For chess, $b \approx 35$, $m \approx 100$ for "reasonable" games ⇒ exact solution completely infeasible

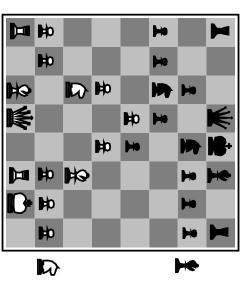

Resource limits

Suppose we have 100 seconds, explore 10^4 nodes/second $\Rightarrow 10^6$ nodes per move

Standard approach:

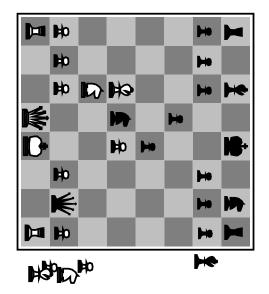

- cutoff test e.g., depth limit (perhaps add quiescence search)
- evaluation function
 = estimated desirability of position

Evaluation functions

Black to move

White slightly better

White to move

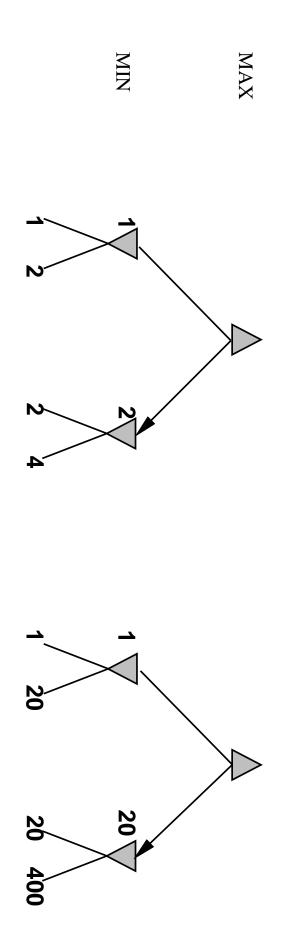

Black winning

For chess, typically linear weighted sum of features

EVAL
$$(s) = w_1 f_1(s) + w_2 f_2(s) + ... + w_n f_n(s)$$

 $f_1(s) =$ (number of white queens) - (number of black queens) e.g., $w_1 = 9$ with

igression: Exact values don't matter

Behaviour is preserved under any monotonic transformation of ${
m EVAL}$

Only the order matters:

payoff in deterministic games acts as an ordinal utility function

Cutting off search

 $\operatorname{MinimaxCutoff}$ is identical to $\operatorname{MinimaxValue}$ except

- 1. Terminal? is replaced by Cutoff?
- 2. UTILITY is replaced by EVAL

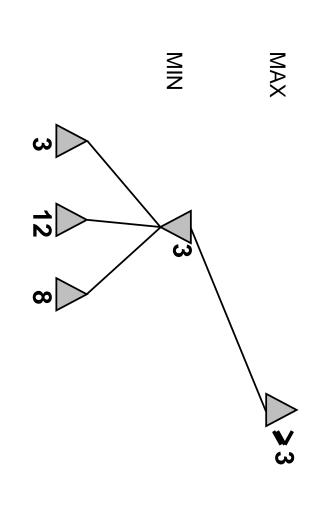

Does it work in practice?

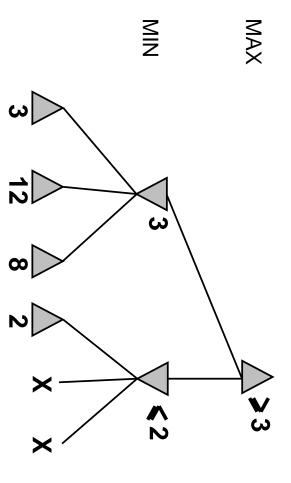

$$b^m = 10^6, \quad b = 35 \quad \Rightarrow \quad m =$$

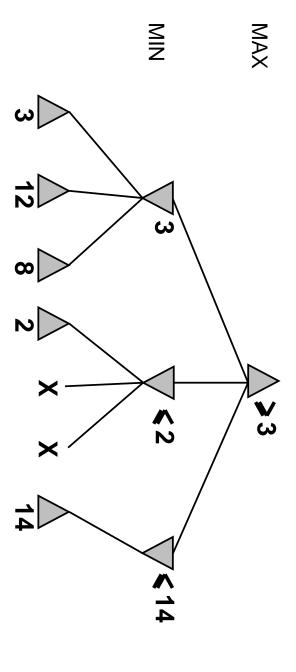

4-ply lookahead is a hopeless chess player!

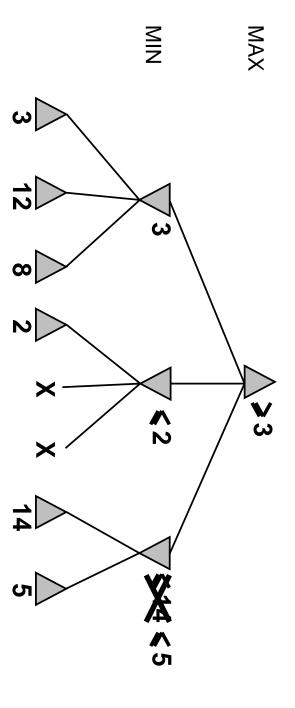

4-ply \approx human novice 8-ply \approx typical PC, human master 12-ply \approx Deep Blue, Kasparov

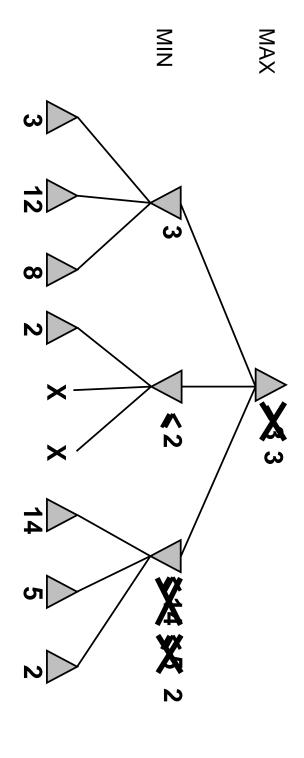

$-\beta$ pruning example

Properties of $n\!-\!\beta$

Pruning does not affect final result

Good move ordering improves effectiveness of pruning

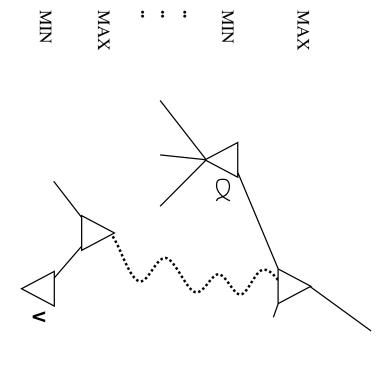

With "perfect ordering," time complexity = $O(b^{m/2})$

 $\Rightarrow doubles$ depth of search

⇒ can easily reach depth 8 and play good chess

are relevant (a form of metareasoning) A simple example of the value of reasoning about which computations

Why is it called $n-\beta$?

Define β similarly for MIN If V is worse than α , MAX will avoid it \Rightarrow prune that branch $^{\circ}$ is the best value (to MAX) found so far off the current path

The $n-\beta$ algorithm

Basically MINIMAX + keep track of α , β + prune

```
function Min-Value(state, game, \alpha, \beta) returns the minimax value of state
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     function Max-Value(state, game, \alpha, \beta) returns the minimax value of state
                                                        \operatorname{end}
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        end
return \beta
                                                                                                                                                                                                       for each s in Successors(state) do
                                                                                                                                                                                                                                                      if Cutoff-Test(state) then return Eval(state)
                                                                                                                                                                                                                                                                                                                                                                                                                                       return \alpha
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            for each s in Successors(state) do
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       if Cutoff-Test(state) then return Eval(state)

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              \beta, the best score for MIN along the path to state
```

eterministic games in practice

443,748,401,247 positions tor all positions involving 8 or fewer pieces on the board, a total of ion Tinsley in 1994. Used an endgame database defining perfect play Checkers: Chinook ended 40-year-reign of human world champion Mar-

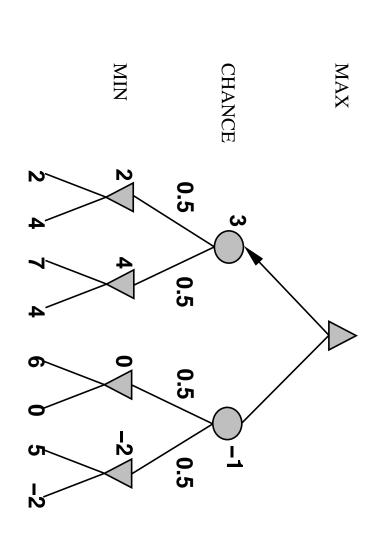

extending some lines of search up to 40 ply. second, uses very sophisticated evaluation, and undisclosed methods for six-game match in 1997. Deep Blue searches 200 million positions per Chess: Deep Blue defeated human world champion Gary Kasparov in a

are too good. Othello: human champions refuse to compete against computers, who

to suggest plausible moves too bad. In go, b > 300, so most programs use pattern knowledge bases Go: human champions refuse to compete against computers, who are

Nondeterministic games

Simplified example with coin-flipping instead of dice-rolling: E..g, in backgammon, the dice rolls determine the legal moves

Algorithm for nondeterministic games

EXPECTIMINIMAX gives perfect play

Just like MINIMAX, except we must also handle chance nodes:

•

if state is a chance node then return average of ExpectiMinimax-Value of Successors(state)

but only if the leaf values are bounded. Why?? A version of α – β pruning is possible

Nondeterministic games in practice

Backgammon \approx 20 legal moves (can be 6,000 with 1-1 roll) Dice rolls increase b: 21 possible rolls with 2 dice

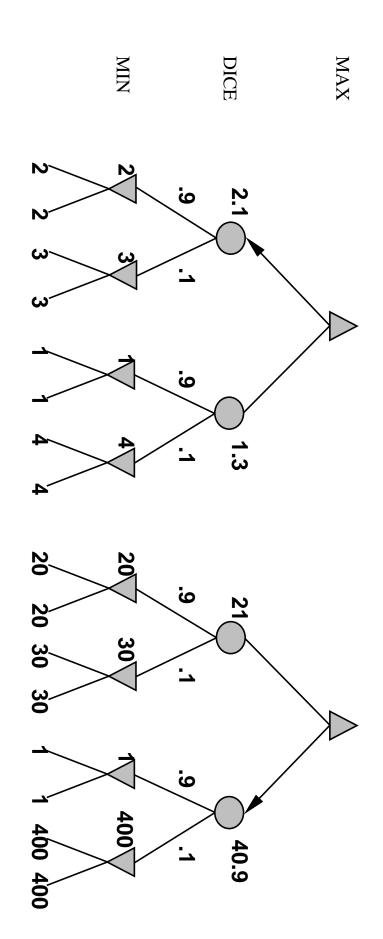

depth
$$4 = 20 \times (21 \times 20)^3 \approx 1.2 \times 10^9$$

As depth increases, probability of reaching a given node shrinks ⇒ value of lookahead is diminished

 $\alpha\text{--}\beta$ pruning is much less effective

TDGAMMON uses depth-2 search + very good EVAL pprox world-champion level

gression: Exact values matter

Behaviour is preserved only by $positive\ linear$ transformation of EVAL Hence EVAL should be proportional to the expected payoff

Summary

Games are fun to work on! (and dangerous)

They illustrate several important points about Al

- \Diamond perfection is unattainable \Rightarrow must approximate
- good idea to think about what to think about
- \diamondsuit uncertainty constrains the assignment of values to states

Games are to AI as grand prix racing is to automobile design
